Introduction

A-type lamins (lamins A and C) are type-V intermediate filaments that form the nuclear lamina, a proteinaceous meshwork underlying the inner nuclear membrane, which also extends throughout the nucleoplasm. They are major contributors to nuclear shape and architecture.1-3 Lamins A and C arise as different mature proteins through alternative splicing of the \textit{LMNA} gene and post-translational modifications. Lamin \textit{A} is synthesized as a prelamin \textit{A} precursor that undergoes farnesylation and carboxymethylation at the CAAX motif at the carboxyl terminus, followed by proteolytic cleavage of 15 amino acids, including the modified terminal cysteine. A-type lamins have been implicated in many essential nuclear processes, including DNA replication and repair, gene transcription and chromatin remodeling and nuclear envelope breakdown and reassembly during mitosis.4-6

Lamins have been implicated in many essential nuclear processes, including DNA replication and repair, gene transcription and chromatin remodeling and nuclear envelope breakdown and reassembly during mitosis.4-6

Over 300 mutations in the \textit{LMNA} gene, encoding A-type lamins, are associated with 15 human degenerative disorders and premature aging syndromes. Although genomic instability seems to contribute to the pathophysiology of some laminopathies, there is limited information about what mutations cause genomic instability and by which molecular mechanisms. Mouse embryonic fibroblasts depleted of A-type lamins or expressing mutants lacking exons 8–11 (\textit{Lmna}Δ8–11/Δ8–11) exhibit alterations in telomere biology and DNA repair caused by cathepsin L-mediated degradation of 53BP1 and reduced expression of BRCA1 and RAD51. Thus, a region encompassing exons 8–11 seems essential for genome integrity. Given that deletion of lamin \textit{A} exon 9 in the mouse (\textit{Lmna}Δ9/Δ9) results in a progeria phenotype, we tested if this domain is important for genome integrity. \textit{Lmna}Δ9/Δ9 MEFs exhibit telomere shortening and heterochromatin alterations but do not activate cathepsin L-mediated degradation of 53BP1 and maintain expression of BRCA1 and RAD51. Accordingly, \textit{Lmna}Δ9/Δ9 MEFs do not present genomic instability, and expression of mutant lamin \textit{A} Δexon9 in lamin-depleted cells restores DNA repair factors levels and partially rescues nuclear abnormalities. These data reveal that the domain encoded by exon 9 is important to maintain telomere homeostasis and heterochromatin structure but does not play a role in DNA repair, thus pointing to other exons in the lamin \textit{A} tail as responsible for the genomic instability phenotype in \textit{Lmna}Δ9/Δ9 mice. Our study also suggests that the levels of DNA repair factors 53BP1, BRCA1 and RAD51 could potentially serve as biomarkers to identify laminopathies that present with genomic instability.

Laminopathies are diseases caused by mutations in genes encoding proteins of the nuclear lamina.6-7 In particular, over 300 mutations have been identified in the \textit{LMNA} gene that are associated with a variety of human diseases,6 ranging from muscular and adipose tissue dystrophies to premature aging syndromes such as Hutchinson-Gilford progeria syndrome (HGPS).8,9 Although it is clear that A-type lamins are critical for nuclear function, the molecular mechanisms affected by the different mutations in the A-type lamins and how they contribute to the broad variety of diseases remain ill defined.10 Mouse models of laminopathies have been instrumental to understand the molecular basis of these diseases.6,10-13 The \textit{Lmna}Δ9/Δ9 Δexon7 mouse model is one of the best-characterized.12 Originally generated as a knockout of A-type lamins, a recent study showed that it is not a complete knockout13 and that low levels of a truncated form of lamin \textit{A} are produced lacking the domain encoded for by exons 8–11 of the \textit{LMNA} gene. These mice develop abnormalities that resemble human Emery-Dreifuss muscular dystrophy.
muscular dystrophy and die at 5–6 weeks of age with severe growth retardation and cardiomyopathy. In addition, several mouse models of progeria have been generated to study HGPS. Most HGPS cases are caused by a splicing defect in exon 11 of the Lmna gene. A substitution of C to T at nucleotide 1824 (G608G) introduces a cryptic donor splice site that results in the deletion of 50 amino acids near the carboxyl-terminus of lamin A. This altered form of lamin A, known as progerin, is toxic to the cells. Mice homozygous for this mutation (G608G in mice) exhibit growth retardation and premature death at around 100 days. Another premature aging mouse, Zmpste24 knockout, lacks the metalloprotease that cleaves the farnesylated tail of prelamin A and absence of mature lamin A. These mice die at five months and exhibit growth retardation, skeletal defects, cardiomyopathy, muscular dystrophy, lipodystrophy, and a progeroid phenotype. A different mouse model was generated by introducing a point mutation in exon 9 of the Lmna gene that caused mRNA splicing defects and deletion of exon 9 (herein LmnaΔ8–11), which is accompanied by low levels of mutant lamin A/C transcripts and proteins. The LmnaΔ8–11 mouse shares many tissues and molecular pathologies characteristic of progeria, with severe growth retardation and death within 3–4 weeks, but with no evidence of muscular dystrophy. Thus, these mice present a phenotype that is significantly different from LmnaΔ9/Δ9 mice.

At the cellular level, common defects in the laminopathies include ultrastructural defects of the nuclear envelope, loss of heterochromatin from the nuclear periphery, alterations in epigenetic marks characteristic of constitutive heterochromatin and increased genomic instability. Our previous studies demonstrated that LmnaΔ8–11/Δ9 MEFs exhibit defects in the two main mechanisms of DNA double-strand break (DSB) repair: non-homologous end-joining (NHEJ) and homologous recombination (HR). In particular, these mutant MEFS activate cathepsin L-mediated degradation of 53BP1 and downregulate transcription of BRCA1 and RAD51 genes. As a consequence, LmnaΔ8–11/Δ9 MEFS exhibit defects in the main mechanisms of DNA double-strand break repair: non-homologous end-joining (NHEJ) and homologous recombination (HR).

Here, we used MEFS from LmnaΔ8–11/Δ9 mice to determine if the domain of A-type lamins encoded for by exon 9 is important for the maintenance of genome stability. We find that LmnaΔ9/Δ9 MEFS present with telomere and chromatin defects but not genomic instability. Interestingly, expression of mutant lamin A Δexon9 protein is able to maintain normal levels of the DNA repair factors 53BP1, BRCA1, and RAD51, as well as rescue DNA repair defects in A-type lamin-depleted cells. Our study suggests that the domain encoded for by exon 9 is not critical for DNA repair, and that the levels of DNA repair factors such as 53BP1, BRCA1 and RAD51 have the potential to serve as biomarkers to identify laminopathy patients with genomic instability.

**Results**

**Telomere shortening in LmnaΔ8–11 mice**

We previously showed that LmnaΔ8–11/Δ9 MEFS exhibit telomere shortening and complete telomere losses. Here, we determined if LmnaΔ8–11 MEFS are compromised in their ability to maintain telomere length homeostasis. Since previous studies showed that lamin A/C transcripts carrying the Δexon9 mutation are not stable, we first confirmed the global decrease of mutant lamin A/C proteins in MEFS isolated from these mice (Fig. S1).

Next, we measured telomere length by telomere restriction fragment (TRF) analysis and quantitative fluorescence in situ hybridization (Q-FISH) analysis (Figs. 1A and B). LmnaΔ8–11 MEFS show a clear faster migration of telomeres by TRF compared with wild-type, indicative of shorter telomere tracks. These results were confirmed by Q-FISH assays, which show an average telomere length approximately 6 Kb shorter in LmnaΔ8–11 MEFS than in wild-type MEFS (Fig. 1B). In addition, a 50–75% decrease in the percentage of long telomeres (≥65 Kb) was observed in LmnaΔ8–11 MEFS. Statistical analysis shows that these differences in telomere length between genotypes are significant (P = 0.0181). These data demonstrate that low expression of the lamin A Δexon9 form leads to defects in the maintenance of telomere length homeostasis, recapitulating the defects observed in LmnaΔ9/Δ9 MEFS and in MEFS depleted of A-type lamins via lentiviral transduction with specific siRNAs. Thus, alterations in A-type lamins, via depletion or expression of mutant lamins, result in faster telomere attrition, which if recapitated in human cells, could limit cell proliferation over time.

**Telomeric and pericentric heterochromatin structure is altered in LmnaΔ8–11 fibroblasts**

Telomeric and pericentric domains have epigenetic modifications characteristic of heterochromatin, including trimethylation of histone H3 at lysine 9 (H3K9me3) and of histone H4 at lysine 20 (H4K20me3). We previously found that expression of Δexon8–11 mutant lamins affects the epigenetic status of telomeric and pericentric chromatin. In particular, decreased levels of H4K20me3 at both domains were observed in LmnaΔ8–11/Δ9 fibroblasts. To determine if MEFS from the LmnaΔ8–11 mouse model exhibit alterations in the structure of telomeric heterochromatin we performed chromatin immunoprecipitation (ChIP) assays with antibodies recognizing H3K9me3 and H4K20me3 marks (Fig. 1C). We found a 40% decrease in the levels of both heterochromatic marks at telomeres in LmnaΔ8–11 cells (Fig. 1D). Collectively, these data support a role for A-type lamins in the maintenance of telomeric chromatin structure, with specific mutations in A-type lamins having differential impacts on the epigenetic status of telomeres.

Alterations of telomeric chromatin structure are often phenocopied by pericentric heterochromatin. Such is the case of LmnaΔ9/Δ9 MEFS, which show reduced levels of H4K20me3 at pericentric domains. To determine the levels of H3K9me3 and H4K20me3 at pericentric chromatin in LmnaΔ8–11 fibroblasts, the membranes hybridized with a telomeric probe were stripped and rehybridized with a probe recognizing major satellite sequences. Interestingly, while the levels of H3K9me3 at pericentric chromatin were also reduced in the mutant cells (albeit to a lower extent than at telomeric chromatin), the levels of H4K20me3 were maintained in the mutant cells at these domains (Fig. 1C). Our results indicate specificity with respect
to epigenetic changes at telomeric vs. pericentric chromatin in LmnaΔ9/Δ9 MEFs. Furthermore, comparing global levels of heterochromatic marks between LmnaΔ8–11/Δ8–11 and LmnaΔ9/Δ9 MEFs by western revealed a global decrease of H4K20me3 in LmnaΔ8–11/Δ8–11 MEFs and a global decrease in both H3K9me3 and H4K20me3 in LmnaΔ9/Δ9 MEFs (Fig. 1E).

Mutations in the LMNA gene and reduced lamin expression are associated with loss of heterochromatin from the nuclear periphery. In mouse cells, heterochromatic domains, especially pericentric regions, are easily visualized by DAPI staining during interphase. In normal fibroblasts, pericentric domains appear as DAPI-positive clusters called chromocenters that are
enriched in H3K9me3 and H4K20me3 marks. We performed immunofluorescence studies to test if expression of Δexon9 lamin A mutant protein affects the structure and distribution of heterochromatin domains within the nucleus. We found that in mutant cells, DAPI staining is distributed throughout the nucleoplasm, exhibiting only a few areas of compacted pericentric chromatin (Fig. 1f). Labeling with antibodies recognizing H3K9me3 and H4K20me3 mirrored the DAPI distribution, such that the heterochromatin marks in mutant cells were either distributed more diffusely throughout the nucleus or forming a few large aggregates. Overall, these studies indicate that low expression of the lamin A Δexon9 mutant protein leads to a decrease in heterochromatic marks at telomeres and an overall disorganization of pericentric chromatin domains. These results support a role for the domain encoded by exon 9 of the LMNA gene in the nuclear compartmentalization of heterochromatin.

Figure 2. Degree of genomic instability in \textit{Lmna}Δ9/Δ9 MEFs. (A) Genomic instability was monitored in wild-type and \textit{Lmna}Δ9/Δ9 MEFs by counting percentage of metaphase spreads showing single telomere losses (STL), chromosome end-to-end fusions, chromosome and chromatid breaks and other complex aberrations. Images show examples of chromosomal aberrations. Note that \textit{Lmna}Δ9/Δ9 fibroblasts do not show a marked increase in genomic instability. (B) Quantitation of percentage of cells presenting with basal levels of DNA damage, as assessed by the presence of >5 γH2AX foci by immunofluorescence. n, total number of cells analyzed. (C) Neutral comet assays were performed in wild-type and \textit{Lmna}Δ9/Δ9 MEFs at different times (0–150 min) post-irradiation with 8 Gy, to compare kinetics of DNA DSB repair. Average "olive moment," a measure of unrepaired DNA damage, was calculated in 3 independent experiments with 25–30 measurements per condition. Bars represent standard deviation. (D) Quantitation of CTSL, 53BP1, BRCA1, and RAD51 transcripts levels by qRT-PCR in wild-type and \textit{Lmna}Δ9/Δ9 MEFs. (E) Western blots to monitor levels of 53BP1, BRCA1, RAD51, and CTSL proteins in MEFs from \textit{Lmna}Δ8–11/Δ8–11, \textit{Lmna}Δ9/Δ9 and their corresponding wild-type littermates. β-Tubulin was used as loading control.
Fibroblasts from *LmnaΔ9/**Δ**10* mice do not exhibit profound genomic instability.

Alterations of telomere biology and defects in DNA repair can lead to chromosome end-to-end fusions and other chromosomal aberrations that have serious detrimental effects for the integrity of the genome. *LmnaΔ9/**Δ**10* MEFs feature defective DNA repair pathways and increased basal DNA damage levels, as well as increased chromosomal aberrations. To determine whether the domain encoded by exon 9 is important for the maintenance of genome stability, we tested whether degradation of 53BP1 protein, and reduced expression of BRCA1 and RAD51 genes. We tested whether 53BP1 protein, as well as a marked reduction in BRCA1 and RAD51 mRNA and protein, as previously reported. Next, we performed retroviral transduction of lamin-deficient cells with an empty vector control (EV), wild-type lamin A (LA) or the mutant lamin A Δexon9 (ΔEx9LA) construct. Interestingly, expression of both proteins reduced the global levels of CTSL and rescued the levels of 53BP1, BRCA1 and RAD51 proteins (Fig. 3A). Monitoring the levels of transcripts of these DNA repair factors revealed that ΔEx9LA protein expression counteracts the transcriptional activation of CTSL and the repression of BRCA1 and RAD51 observed in lamin-depleted cells (Fig. 3B). Furthermore, previous studies had shown that loss of A-type lamins leads to degradation of Rb family members p107 and p107 with no effect on p16INK4a. Interestingly, reconstitution of a variety of disease-associated lamin mutants into lamin-deficient cells rescued Rb family members and the ability of these cells to respond to p16INK4a-induced growth arrest. Here, we show that reconstitution of ΔEx9LA protein expression also rescues the levels of p107 and p107 proteins in lamin-depleted cells. These results demonstrate that the domain encoded by exon 9 in the *LAMA4* gene is not necessary to maintain transcription and stabilization of DNA repair factors and cell cycle proteins regulated by A-type lamins.

To determine if lamin mutants associated with genomic instability are able to rescue the levels of DNA repair factors, we reconstituted the mutant lamin A protein that is expressed in HGPS patients (G608G) (Fig. 3C). Intriguingly, we found that after passing the cells for approximately two weeks, G608G cells were able to rescue to certain extent the levels of CTSL and 53BP1. In contrast, cells expressing G608GGLA exhibit as lower levels of BRCA1, RAD51, p107 and p107 proteins as lamin-deficient cells. These results support the notion that specific mutations in A-type lamins affect the expression and stability of different proteins, thus affecting differentially DNA repair mechanisms, genomic stability and cell cycle regulation.

Altogether, our data indicate that cells expressing ΔEx9LA mutant protein are able to maintain the levels of key factors in the maintenance of genomic stability. Supporting this conclusion, expression of ΔEx9LA mutant protein reduced the basal levels of unrepaired DNA damage in lamin-depleted cells, as monitored by γH2AX foci (4A and B). In addition, ΔEx9LA mutant protein reduced the extent of nuclear morphological abnormalities, as monitored by DAPI (4A and B), to a similar extent as wild-type lamin A protein. In summary, we show that the domain encoded for by exon 9 in the *LAMA4* gene affects telomere homeostasis and heterochromatin structure, without having a major role in the maintenance of DNA repair and genome stability.
Discussion

The broad range of diseases associated with either mutations in the LMNA gene or changes in the expression of A-type lamins has drawn much attention toward elucidating the functions of these structural nuclear proteins. Several lines of evidence indicate that lamin-related diseases are associated with increased genomic instability. The notion that defects in the maintenance of telomeres and in DNA repair contribute to the pathophysiology of these diseases has been gaining momentum. However, the data supporting this notion remains scarce. Our previous studies showed that lamin A/C-expressing fibroblasts exhibit defects in telomere structure, length, and function, increased chromosome and chromatid breaks, a higher degree of unrepaired DNA damage, and an overall increase in genomic instability. The activation of CTSL-mediated degradation of 53BP1 and the transcriptional downregulation of BRCA1 and RAD51 genes are mechanisms underlying the genomic instability in these cells. These results support the notion that increased genomic instability contributes to the phenotype of some lamin-related diseases. The present study on LmnaΔ8–11/Δ8–11 mice shows, however, that increased genomic instability is not a phenotype shared by all lamin-related diseases. In contrast, alterations of telomere biology and heterochromatin defects are common to many models of laminopathies, although if and how these alterations contribute to the pathophysiology of these diseases remains unknown. Furthermore, our data begins to provide information about domains in A-type lamins that are important for maintenance of DNA repair factors, DNA repair mechanisms and overall genome integrity. In particular, we conclude that the globular tail domain encoded for by exons 8–11 contains features that are critical for the maintenance of genomic instability phenotype. This region, however, plays a key role in the regulation of transcription factors that modulate the deposition of a functional extracellular matrix. Given that a number of mutations in lamin A exon 9 have been linked to diseases such as HGPS (R527C) and muscular dystrophy (L530P), it is tempting to speculate that these mutations could lead to defects in different signaling pathways without affecting genomic stability. Future studies with different disease-associated point mutations or more deletions in this domain will be necessary to delineate the specific region in the globular tail of A-type lamins that is responsible for the genomic instability phenotype.

Defects in chromatin structure

Fibroblasts from HGPS patients exhibit reduced levels of the heterochromatin marks H3K9me3 and H3K27me3, while featuring increased levels of H4K20me3 at pericentric chromatin domains. The defects in HP1 and H3K9me3 have been linked to a reduction of NURD subunits, specifically RBBP4, RBBP7 and HDAC1, which interact with lamin A. The authors found that the loss of NURD subunits in HGPS cells was dependent upon the presence of progerin. It remains to be determined if expression of other mutant lamins

Figure 3. Effect of expression of ΔEx9LA protein on DNA repair factors levels. (A) Wild-type MEFs were lentivirally transduced with shRNA control (shLuc) or shRNA specific for depletion of A-type lamins (shLmna). Subsequently, both types of cells were retrovirally transduced with an empty vector control (EV), and lamins-depleted cells were transduced with wild-type lamin A (LA) or with ΔEx9LA mutant protein. Western blots were performed to monitor levels of proteins regulated by lamins (53BP1, BRCA1, RAD51, CTSL, and Rb family members). β-Tubulin was used as loading control. Note the marked depletion of lamin A/C by shLmna, and the reconstitution of wild-type and mutant lamin A (showing lower Mr). (B) Quantitation of CTSL, 53BP1, BRCA1, and RAD51 transcripts levels by qRT-PCR in lamins-proficient and -deficient cells in which wild-type LA or ΔEx9LA mutant proteins were reconstituted. Graph shows average of 3 independent experiments (each conducted in triplicate), and bars represent standard deviation. P represents value of statistical significance. When P ≤ 0.05, differences are considered significant and labeled with asterisk (*). (C) Western blots were performed in lamins-proficient (shLuc+EV), lamins-deficient cells (shLmna+EV) and lamins-deficient cells expressing the G608G mutant form of lamin A. The levels of DNA repair factors and Rb family members regulated by lamins were detected.
In the present study we show that, in addition to the defects in histone marks, we observed that pericentric chromatin will require further investigation. Of fibroblasts to maintain H4K20me3 levels at pericentric but not telomeric chromatin. Interestingly, pericentric chromatin exhibit decreased H3K9me3 and H4K20me3, which are recapitulated in telomeric domains.24 The concomitant destabilization of Rb family members in LmnaΔ8–11 fibroblasts do not show decreased H3K9me3 at heterochromatic domains. Thus, this mutant form of lamins might not affect the expression of NURD factors. In contrast, we found a marked decrease in H4K20me3 levels at these domains.25 The concomitant destabilization of Rb family members in LmnaΔ8–11 fibroblasts could be responsible for this defect.27 In the present study we show that LmnaΔ8–11 fibroblasts exhibit yet a different pattern of defects in histone marks. LmnaΔ8–11 fibroblasts have decreased global levels of both H3K9me3 and H4K20me3, which are recapitulated in telomeric domains. Interestingly, pericentric chromatin exhibit decreased levels of H3K9me3, while maintaining H4K20me3 levels. Understanding the molecular mechanisms that allow LmnaΔ8–11 fibroblasts to maintain H4K20me3 levels at pericentric but not telomeric chromatin will require further investigation. Of note, in addition to the defects in histone marks, we observed alterations in the structure of pericentric heterochromatin in LmnaΔ9/Δ9 cells. Altogether, these studies indicate that A-type lamins play a key role in the maintenance of heterochromatin domains, with different alterations in these proteins impacting on specific chromatin-modifying activities.

Defects in telomere biology

Alterations of telomere biology have been associated with lamin-related diseases. However, the available data shows clear differences between the different models studied. While HGPS fibroblasts undergo faster telomere attrition during proliferation, Zmpste24Δ/Δ cells maintain telomere length homeostasis.25 In LmnaΔ8–11/Δ8–11, we observed both telomere shortening and telomere deletions. Interestingly, LmnaΔ8–11 fibroblasts show telomere attrition but not a significant increase in STL.

Maintenance of telomere length and stability is a complex process that requires proper accessibility of telomeres to replicating telomeres and assembly of the shelterin complex after replication. The shelterin complex facilitates the formation of a T-loop structure at the end of the chromosome, which prevents NHEJ or HR events involving telomeres. We envision that the expression of lamin A Δexon9 mutant proteins might hinder the accessibility of telomerase, while expression of lamin A Δexon8–11 could affect both telomere accessibility and telomere replication and/or repair, leading to terminal deletions. These differences suggest that specific mutations in the LMNA gene impact differentially on telomere maintenance mechanisms. However, we find it unlikely that the telomere defects play a major role in the phenotype of mouse models of laminopathies, given that in most cases the defects are modest. Other processes such as defects in DNA repair, cell cycle regulation and signaling pathways that condition the extracellular environment could possibly have a major contribution to the pathophysiology of these diseases.

Genomic instability in the laminopathies

Increased genomic instability has been observed in LmnaΔ8–11/Δ8–11 fibroblasts. In contrast, no evidence of increased genomic instability was found in LmnaΔ9/Δ9 fibroblasts. A striking difference between these genotypes is their ability to stabilize 53BP1 and maintain expression of BRCA1 and RAD51. We found that the levels of 53BP1, BRCA1 and RAD51 are markedly reduced in LmnaΔ8–11/Δ8–11 and lamin-depleted fibroblasts but not in LmnaΔ9/Δ9 fibroblasts. Overall, these studies provide new insights about how different mutations in lamin A impact specific molecular mechanisms responsible for the maintenance of genome integrity.

The DNA repair factors 53BP1, BRCA1 and RAD51 remain unknown. However, it is clear that transcription of these genes is affected by specific lamin mutations. It is plausible that the localization of these genes in the 3D nuclear space is affected by the mutant laminas, as shown for a number of

**Figure 4.** Expression of ΔEx9LA partially rescues phenotypes of lamin-deficient cells. (A) Quantitation of cells presenting with >5 γH2AX foci, indicating basal levels of unrepaired DNA damage, as well as cells exhibiting nuclear morphological abnormalities by DAPI staining. Cells analyzed include MEFs transduced with control shRNA and empty vector (shLucEV); MEFs transduced with shRNA for lamin depletion and empty vector (shLmna+EV), as well as lamin-deficient MEFs in which LA or ΔEx9LA proteins were reconstituted (shLmna+LA and shLmna+ΔEx9LA). These hundred cells were analyzed per condition. Note how ΔEx9LA expression partially rescues both phenotypes. (B) Images from the immunofluorescence study with γH2AX antibody and DAPI staining in (A).
genes. Alternatively, the effect of lamins mutations in chromatin structure could alter the epigenetic status of these genes, resulting in deregulated transcription. Another possibility is a direct association of lamins with these genes to regulate transcriptional activation or repression. Additional studies need to be performed to identify the mechanisms responsible for these transcriptional changes.

Importantly, this study suggests that levels of 53BP1, BRCA1, and RAD51 could represent biomarkers to screen patients that present with genomic instability. Future studies along this line could represent important advances for therapy.

Materials and Methods

Cell culture
Wild-type, LmnaΔ8–11/Δ8–11 and LmnaΔ9/9 MEFs were generated in the laboratory of Stewart CL. Cells were maintained in DMEM supplemented with 10% FBS, antibiotics and antymycotics.

Ionizing radiation
For IRIF formation, cells were irradiated with 8 Gy and fixed and processed for immunofluorescence 1 h post-irradiation. For comet assays, cells were irradiated with 8 Gy and collected at different times post-irradiation.

Telomere length measurement
TRF
Cells were prepared in agarose plugs and TRF analysis was performed as described. Quantitative FISH
Metaphase stage chromosomal spreads were prepared and hybridized as described. Fluorescent images were taken using a Nikon 90i upright microscope and the intensity of telomere fluorescence was analyzed using the TFL-Telo program (gift from de Lange T, Rockefeller University, NY) or a major satellite probe. The signal was quantitated using the ImageQuant software (Molecular Dynamics). Serial dilutions of the unbound fraction from the no antibody control were processed for inputs. We calculated the amount of telomeric DNA immunoprecipitated relative to the signal of the corresponding inputs. The ChIP values are represented as a percentage of the total input telomeric DNA, therefore correcting for the difference in the number of telomere repeats.

Immunofluorescence
Cells growing in coverslips were processed directly for IF or irradiated with 8 Gy and processed 1 h post-irradiation. Cells were fixed in 3.7% formaldehyde + 0.2% Triton-X 100 in PBS for 10 min at RT and blocked for 1 h at 37 °C in 10% serum in PBS. Incubations with antibodies were performed for 1 h at 37 °C. Washes were performed in PBS and slides were counterstained with DAPI in Vectashield (Vector). Microscopy and photo capture was performed on either a Nikon Eclipse 90i microscope or a Leica DFC500 FX digital camera and the Leica Application Suite (Version 4.1.0). Fluorescence in situ hybridization
FISH was performed on metaphase spreads. Cells were arrested in mitosis by treating with colcemid for 4 h and prepared for FISH by hypotonic swelling in 0.56% KCl followed by fixation in 3:1 methanol:acetic acid. Cell suspensions were dropped onto slides and FISH was performed using a Cy3-telomeric PNA probe, and DNA counterstained using DAPI. Images were taken using a Nikon 90i upright microscope.

Comet assays
Neutral comet assays were performed using CometSlide assay kits (Trevigen). Cells were irradiated with 8 Gy and incubated at 37 °C for different periods of time (0–150 min) to allow for DNA damage repair. Cells were embedded in agarose, lysed and subjected to neutral electrophoresis. Before image analysis, cells were stained with ethidium bromide and visualized under a fluorescence microscope. Single-cell electrophoresis results in a comet-shaped distribution of DNA. The comet head contains high molecular weight and intact DNA, and the tail contains the leading ends of migrating fragments. Olive comet moment was calculated by multiplying the percentage of DNA in the tail by the displacement between the means of the head and tail distributions. We utilized the program CometScore™ Version 1.5 (TriTek) to calculate Olive Comet Moment. A total of 25–30 comets were analyzed per condition in each experiment.

Immunoblotting
Cells were lysed in RIPA buffer (150 mM NaCl, 50 mM Tris-HCl pH 7.4, 1% NP-40, 0.2% SDS, 0.25% sodium deoxycholate and 1 mM EDTA) containing HALT protease and phosphatase inhibitor cocktail (Pierce). Lysates were sheared using 10 passes through a 26-gauge needle followed by 10 passes through a 30-gauge needle. Sixty to 80 µg of total protein were separated by SDS-PAGE on a 4–15% Criterion TGX Gel (Bio-Rad) and transferred to a nitrocellulose membrane using the Trans-Blot Turbo system (Bio-Rad). Membranes were developed using standard ECL technique and used Thermo-Pierce ECL (Pierce) or Millipore Super ECL (EMD Millipore) for BRCA1 detection. A list of antibodies used is provided in the Supplemental Material.

Quantitative reverse-transcription PCR
cDNA was generated by reverse transcription of 1 µg total RNA using the GeneAmp® RNA PCR kit (Applied Biosystems, CA). qRT-PCR was performed using the 7900HT Fast Real-Time
PCR system (Applied Biosystems) with the Taqman Universal PCR Master Mix. Reactions were performed in triplicate and target gene and endogenous controls were amplified in the same plate. Relative quantitative measurements of target genes were determined by comparing the cycle thresholds.

Viral transduction

Retro- and lentiviral transductions were performed as described. Briefly, 293T cells were transfected with viral packaging (pVSVG-CMV, pMD2.G, and envelope plasmids (pCMV-VSV-G)) along with the vector containing the cDNA or shRNA of interest. After 48 h, virus-containing media was harvested to infect target cells (MEFs). Retroviral transductions were performed as two 4–6 h infections on sequential days and lentiviral as one 4 h infection. Cells were allowed to recover for 48 h, and selected with the appropriate drugs. Viral envelope and packaging plasmids were gifts from Sheila Stewart (Washington University). shRNAs were obtained from Sigma-Aldrich, and LA and ΔΔv9LA expression plasmids were generated in Stewart’s laboratory.

Statistical analysis

With the exception of the ChIP experiments, a standard 2-sided, unpaired t-test was used to test for significance. Because the telomeric DNA content in the ChIP assays was always normalized to the DNA content of the wild-type cells, the mean of the ΔΔt Homo was tested using the null hypothesis that the mean equals 100 with degrees of freedom equal to the number of repeats minus 1. Results were considered significant at the 0.05 level.

Disclosure of Potential Conflicts of Interest

No potential conflict of interest was disclosed.

Supplemental Materials

Acknowledgments

We thank Caceres J for technical assistance. Research in the laboratory of Gonzalo S was supported by NICAMS Grant RO1 GM094515-01, DOD BCRP Idea Award BC110089, RDA from Siteman Cancer Center and Presidential Research Award from St Louis University. Gonzalo-Suarez I was recipient of a postdoctoral fellowship from AHA.

Author Contributions

Das A and Goswami DA performed most of the experiments and contributed to the design of the project. Neumann MA, Kreienkamp R, Gonzalo-Suarez I and Redwood AB contributed with some experiments. Stewart CL provided MEFS from the Lmna+/− mouse model, and LA and ΔΔv9LA expression plasmids. Kennedy BK provided G608GLA expression plasmid. Gonzalo S supervised the project and prepared the manuscript.
